
#### Abstract

General Description The MAX8809A/MAX8810A synchronous, 2-/3-/4phase, step-down, current-mode controllers with integrated dual-phase MOSFET drivers provide flexible solutions that fully comply with Intel ${ }^{\circledR}$ VRD11/VRD10 and AMD K8 Rev F CPU core supplies. The flexible design supplies load currents up to 150A for low-voltage CPU core power requirements. A tri-state SEL input is available to configure the VID logic for either the Intel VRD11/VRD10 or AMD K8 Rev F applications. An enable input (EN) is available to disable the IC. True-differential remote output-voltage sensing enables precise regulation at the load by eliminating the effects of trace impedance in the output and return paths. A high-accuracy DAC combined with precision current-sense amplifiers and droop control enable the MAX8809A/MAX8810A to meet the most stringent tolerance requirements of new-generation high-current CPUs. These ICs use either integral or volt-age-positioning feedback control to achieve high out-put-voltage accuracy. The COMP input allows for either positive or negative voltage offsets from the VID code voltage. A powergood signal (VRREADY) is provided for startup sequencing and fault annunciation. The SS/OVP pin enables the programming of the soft-start period, and provides an indication of an overvoltage condition. A soft-stop feature prevents negative voltage spikes on the output at turn-off, eliminating the need for an external Schottky clamp diode. The MAX8809A/MAX8810A incorporate a proprietary "rapid active average" current-mode control scheme for fast and accurate transient-response performance, as well as precise load current sharing. Either the inductor DCR or a resistive current-sensing element is used for current sensing. When used with DCR sensing, rapid active current averaging ( $\mathrm{RA}^{2}$ ) eliminates the tolerance effects of the inductance and associated current-sensing components, providing superior phase current matching, accurate current limit, and precise load-line. The MAX8809A operates as a single-chip, 2-phase solution with integrated drivers. It also provides a 3rdphase PWM output and easily supports 3 -phase design by adding the MAX8552 high-performance driver. The MAX8810A enables up to 4-phase designs by adding the MAX8523 high-performance dual driver for a compact 2-chip solution.

Intel is a registered trademark of Intel Corp.

Features

- VRD11/VRD10 and K8 Rev F Compliant
- $\pm 0.35 \%$ Initial Output Voltage Accuracy
- Dual Integrated Drivers with Integrated Bootstrap Diodes
- Up to 26V Input Voltage
- Adaptive Shoot-Through Protection
- Soft-Start, Soft-Stop, VRREADY Output
- Fast Load Transient Response
- Individual Phase, Fully Temperature-

Compensated Cycle-by-Cycle Average Current Limit

- Current Foldback at Short Circuit
- Voltage Positioning or Integral Feedback
- Differential Remote Voltage Sensing
- Programmable Positive and Negative Offset Voltages
- 150 kHz to 1.2 MHz Switching Frequency per Phase
- NTC-Based, Temperature-Independent Load Line
- Precise Phase Current Sharing
- Programmable Thermal-Monitoring Output (VRHOT)
- 6A Peak MOSFET Drivers
- $0.3 \Omega / 0.85 \Omega$ Low-Side, 0.8 $/ 1.1 \Omega$ High-Side Drivers (typ)
- 40-Pin and 48-Pin Thin QFN Packages

Applications
Desktop PCs
Servers, Workstations
Desknote and LCD PCs
Voltage-Regulator Modules

Stresses beyond those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. These are stress ratings only, and functional operation of the device at these or any other conditions beyond those indicated in the operational sections of the specifications is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

## ELECTRICAL CHARACTERISTICS

Pin Description

| PIN |  | NAME | FUNCTION |
| :---: | :---: | :---: | :---: |
| MAX8809A | MAX8810A |  |  |
| 1 | 48 | VRREADY | Open-Drain, Power-Okay Indicator. VRREADY is an open-drain output that goes high impedance when the output is in regulation. VRREADY pulls low when the output is out of regulation, the IC is in shutdown, or $\mathrm{V}_{\mathrm{CC}}$ is below the UVLO threshold. |
| 2 | 1 | ILIM | Current-Limit Set Input. Connect to the center tap of an external resistor-divider from REF to GND to set the cycle-by-cycle average current-limit threshold. Connect ILIM to VCC to select the default current-limit threshold. |
| 3 | 2 | REF | Internal Reference Output. REF regulates to 2 V . Bypass REF to GND with a $0.1 \mu \mathrm{~F}$ to $1 \mu \mathrm{~F}$ ceramic capacitor. Do not use a capacitor greater than $1 \mu F$. REF sources up to $500 \mu \mathrm{~A}$ for external loads. REF is enabled when $V_{C C}$ is above UVLO regardless of the state of EN . |
| 4 | 3 | COMP | Error-Amplifier Output. Connect COMP to the compensation network to implement either voltage positioning or integral feedback-control. Connect a resistor from COMP to GND to set the offset voltage. See the Loop-Compensation Design section for details on determining the compensation network. |
| 5 | 5 | GND | Analog Ground. Connect GND to the analog ground plane. |
| 6 | 6 | VCC | IC Supply Input. Connect $\mathrm{V}_{\mathrm{CC}}$ to a 4.5 V to 5.5 V power supply. Bypass $\mathrm{V}_{\mathrm{Cc}}$ to GND with a $1 \mu \mathrm{~F}$ or larger ceramic capacitor. |
| 7 | 8 | RS- | Output-Voltage Remote-Sense Negative Input. Connect RS- to the VSS_SEN remotesense point at the load when using the remote sense. Otherwise, connect RS- to GND at the load. |
| 8 | 9 | RS+ | Output-Voltage Remote-Sense Positive Input. Connect RS+ to the VCC_SEN remotesense point at the load when using remote sense. Otherwise, connect RS+ to the output at the load. |

## VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM

 Controllers with Integrated Dual MOSFET DriversPin Description (continued)

| PIN |  | NAME | FUNCTION |
| :---: | :---: | :---: | :---: |
| MAX8809A | MAX8810A |  |  |
| 9 | 11 | OSC | Internal Clock Oscillator Frequency Set Input. Connect a resistor from OSC to GND to set the internal oscillator frequency. See the Setting the Switching Frequency section for determining the resistor value. |
| 10 | 12 | SS/OVP | Soft-Start Program Input and Overvoltage-Protection Fault Flag. Connect a resistor from SS/OVP to GND to set the soft-start period. SS/OVP pulls to VCC during an OVP event to signal the fault condition. See the Soft-Start section for determining the resistor value. |
| 11 | 13 | VRTSET | Temperature Comparator Program Input. Connect a resistor from VRTSET to GND to set the VRHOT temperature threshold. Connect VRTSET to Vcc to disable the VRHOT monitoring feature. See the Temperature Monitoring (VRTSET, VRHOT) section for resistor selection. |
| 12 | 14 | NTC | Temperature-Sensing Input. Connect a $10 \mathrm{k} \Omega$ NTC thermistor between NTC and GND for load-line independent temperature compensation. Connect NTC to $V_{C C}$ to disable the temperature compensation and VRHOT monitoring features. See the Temperature Monitoring (VRTSET, VRHOT) section for more details on selection of the NTC device. |
| 13 | - | CS3- | Phase 3 Current-Sense Negative Input. Connect to the load side of the output currentsensing element. |
| 14 | 17 | CS3+ | Phase 3 Current-Sense Positive Input. Connect CS3+ to the positive side of the output current-sense resistor, or the positive side of the filtering capacitor if inductor DCR current sensing is used. |
| 15 | 18 | CS2+ | Phase 2 Current-Sense Positive Input. Connect CS2+ to the positive side of the output current-sense resistor, or the positive side of the filtering capacitor if inductor DCR current sensing is used. |
| 16 | 19 | CS12- | Phases 1 and 2 Current-Sense Common Negative Input. Connect to the load side of the output current-sensing elements. |
| 17 | 20 | CS1+ | Phase 1 Current-Sense Positive Input. Connect CS1+ to the positive side of the output current-sense resistor, or the positive side of the filtering capacitor if inductor DCR current sensing is used. |
| 18 | 21 | EN | Enable Input. Drive EN high to enable the IC. Drive EN low to place the IC in shutdown mode. If $\mathrm{V}_{\mathrm{CC}}$ is greater than the UVLO threshold, EN is internally pulled to $\mathrm{V}_{\mathrm{CC}}$ with a $100 \mathrm{k} \Omega$ resistor. If $\mathrm{V}_{\mathrm{C}}$ is less than the UVLO threshold, EN is internally pulled to GND with a $2 k \Omega$ resistor. |
| 19 | 23 | PWM3 | PWM Signal Output for phase 3. PWM3 is low during shutdown, UVLO, and OVP faults. Connect PWM3 to VCc to enable 2-phase operation. |
| 20 | 24 | VRHOT | Temperature Fault Flag. VRHOT is an active-high, open-drain output that goes high impedance when the temperature sensed by the thermistor at NTC exceeds the temperature threshold programmed at VRTSET. |
| 21 | 25 | DH1 | Phase 1 High-Side MOSFET Gate-Drive Output. Connect to the gate of the high-side MOSFET for phase 1. DH1 is pulled low during shutdown, UVLO, and OVP faults. |
| 22 | 26 | LX1 | Phase 1 Inductor Sense Point. Connect LX1 to the switched side of the inductor for phase 1. |

# VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers 

Pin Description (continued)

| PIN |  | NAME | FUNCTION |
| :---: | :---: | :---: | :---: |
| MAX8809A | MAX8810A |  |  |
| 23 | 27 | BST1 | Phase 1 High-Side MOSFET Gate-Drive Supply. Connect a $0.22 \mu \mathrm{~F}$ or larger ceramic capacitor from BST1 to LX1 to supply gate drive for the high-side MOSFET. See the Boost Capacitor Selection section for details on calculating the BST1 capacitor value. |
| 24 | 28 | DL1 | Phase 1 Low-Side MOSFET Gate-Drive Output. Connect to the gate of the low-side MOSFET for phase 1. DL1 is pulled low during undervoltage lockout and pulled high during an OVP fault. DL1 is high in shutdown if $\mathrm{V}_{\mathrm{CC}}$ is greater than the UVLO threshold. |
| 25 | 29 | PGND1 | Power Ground for the Phase 1 Driver. Connect PGND1 to the source of the phase 1 low-side MOSFET. PGND1 must be connected to PGND2 and GND externally. See the PC Board Layout Guidelines section for more details. |
| 26 | - | VL12 | Phase 1 and 2 Low-Side MOSFET Gate-Drive Supply. Connect VL12 to a 4.5 V to 6.5 V supply. Bypass VL12 with a $2.2 \mu \mathrm{~F}$ or larger ceramic capacitor to the power ground plane. |
| 27 | 32 | PGND2 | Power Ground for the Phase 2 Driver. Connect PGND2 to the source of the phase 2 low-side MOSFET. PGND2 must be connected to PGND1 and GND externally. See the PC Board Layout Guidelines section for more details. |
| 28 | 33 | DL2 | Phase 2 Low-Side MOSFET Gate-Drive Output. Connect to the gate of the low-side MOSFET for phase 2. DL2 is pulled low during undervoltage lockout and pulled high during an OVP fault. DL2 is high in shutdown if $\mathrm{V}_{\mathrm{CC}}$ is greater than the UVLO threshold. |
| 29 | 34 | BST2 | Phase 2 High-Side MOSFET Gate-Drive Supply. Connect a $0.22 \mu \mathrm{~F}$ or larger ceramic capacitor from BST2 to LX2 to supply gate drive for the high-side MOSFET. See the Boost Capacitor Selection section for details on calculating the BST2 capacitor value. |
| 30 | 35 | LX2 | Phase 2 Inductor Sense Point. Connect LX2 to the switched side of the inductor for phase 2. |
| 31 | 36 | DH2 | Phase 2 High-Side MOSFET Gate-Drive Output. Connect to the gate of the high-side MOSFET for Phase 2. DH2 is pulled low during shutdown, UVLO, and OVP faults. |
| 32 | 38 | SEL | VID Table Selection Input. Connect SEL to GND to select the VRD10 VID code (Table 5). Connect SEL to VCC to select the VRD11 8-bit VID code (Table 6). Leave SEL unconnected to select the K8 Rev F VID code (Table 4). |
| 33-40 | 39-46 | VID7-VID0 | Voltage Identification Code Inputs. Use VID_ to set the output voltage. SEL selects the VRD10, VRD11, or K8 Rev F VID logic codes. Connect VID_ to the system VTT with a $680 \Omega$ resistor for logic-high for Intel VR solutions. Connect VID_ to the system VDDQ with a $1 \mathrm{k} \Omega$ resistor for logic-high for AMD VR solutions. |

## Detailed Description

The MAX8809A/MAX8810A synchronous, 2-/3-/4phase, step-down, current-mode controllers with integrated dual-phase MOSFET drivers provide flexible solutions that fully comply with Intel VRD11/VRD10 and AMD K8 Rev F CPU core supplies. The flexible design supplies load currents of up to 150A for low-voltage CPU core power supplies.
The MAX8809A is suitable for 2 - or 3-phase core supply applications. With an integrated dual-MOSFET driver, the MAX8809A offers a single-chip IC solution for dual-phase core supplies. Together with the MAX8552, a high-performance single-phase MOSFET driver, the MAX8809A also supports 3-phase core supplies. Similarly, the MAX8810A features a single IC solution for dual-phase core supplies. It also features two-IC solutions for 3- or 4-phase core supplies by adding a single MOSFET driver (MAX8552) or a dual-MOSFET driver (MAX8523).

Both the MAX8809A and MAX8810A fully comply with Intel VRD11, Extended VRD10, and the AMD K8 Rev F VID codes. The SEL input allows the user to select the architecture specifications.

Clock Frequency (OSC)
An external resistor, ROSC, from OSC to GND sets the internal clock frequency of the MAX8809A/MAX8810A. A $1 \%$ resistor is recommended to maintain good frequency accuracy. The internal clock frequency sets the per-phase switching frequency. The selection of switching frequency per phase is influenced by factors such as the switching speed of the MOSFETs, the inductor's core material, different types of input and output capacitors, and the available board space. Once the perphase switching frequency is selected, the internal clock frequency is determined using the procedure in the Setting the Switching Frequency section.

# VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers 

#### Abstract

Voltage Reference (REF) A precision 2 V reference is provided by the MAX8809A/ MAX8810A at the REF output. REF is capable of sinking and sourcing up to $500 \mu \mathrm{~A}$ for external loads. Connect a $0.1 \mu \mathrm{~F}$ to $1 \mu \mathrm{~F}$ ceramic capacitor from REF to GND. Internal REFOK circuitry monitors the reference voltage. The reference voltage must be above the REFOK threshold of 1.84 V to activate the controller. The controller is disabled if the reference voltage falls below 1.74 V .

Output Current Sensing (CS_+, CS_-)
The output current of each phase is sensed differentially. A low-offset-voltage, differential-current amplifier (30V/V) at each phase allows low-resistance currentsense resistors to be used to minimize power dissipation. Sensing the current at the output of each phase offers advantages including less noise sensitivity, more accurate current sharing between phases, and the flexibility of using either a current-sense resistor or the DC resistance of the output inductor.
Using the DC resistance, RDC, of the output inductor (Figure 3) allows higher efficiency. In this configuration, the initial tolerance and temperature coefficient of $R_{D C}$ must be accounted for in the output-voltage droop-error budget. The temperature coefficient can be compensated; see the Load-Line Independent Inductor DC Resistance Temperature Compensation section for more details. An RC-filtering network is needed to extract the current information from the output inductor. The time constant of the RC network is calculated as follows:

$$
\mathrm{R} 1 \times \mathrm{C} 1=\frac{\mathrm{L}}{\mathrm{R}_{\mathrm{DC}}}
$$

where $L$ is the inductance of the output inductor. For 20A or higher current-per-phase applications, the DC resistance of commercially available inductors is approximately $1 \mathrm{~m} \Omega$. To minimize current-sense error due to the bias current at the current-sense inputs, choose R1 less than $2 k \Omega$. Determine the value for C1 as:

Figure 3. Inductor RDC Current Sense

$$
C 1=\frac{L}{\left(R_{D C} \times R 1\right)}
$$

Select a 1\% resistor for R1. For mainstream PCs 20\% tolerance is recommended for C1, and for performance PCs 10\% tolerance should be considered. If using an inductor with RDC greater than $1 \mathrm{~m} \Omega$, a resistor (R2) may be necessary to divide down the voltage across CS_+ and CS_-. The maximum average signal present at the input of the current-sense amplifier should not exceed 85 mV .
When a current-sense resistor is used for more accurate current sharing and load-line, a similar RC-filtering circuit is recommended to cancel the equivalent series inductance of the current-sense resistor, as shown in Figure 4. Again, select R2 less than $2 k \Omega$, and $C 2$ is determined by the following equation:

$$
\mathrm{C} 2=\frac{\mathrm{ESL}}{\left(\mathrm{R}_{\mathrm{S}} \times \mathrm{R} 2\right)}
$$

where ESL is the equivalent series inductance of the current-sense resistor and RS is the value of the cur-rent-sense resistor. For example, a $1 \mathrm{~m} \Omega, 2025$ package sense resistor has an ESL of 1.6 nH . If using an RS greater than $1 \mathrm{~m} \Omega$, a resistor (R2) may be necessary to divide down the voltage across CS_+ and CS_-. The maximum average signal present at the input of the current-sense amplifier should not exceed 85 mV .

## Output Current Limit and Short-Circuit Protection (ILIM)

The MAX8809A/MAX8810A feature a precise average output current limit on a cycle-by-cycle basis using Maxim's proprietary RA2 technology. The current-limit scheme is insensitive to input-voltage variation, the inductor tolerance, and the tolerance of the currentsense capacitor, permitting the use of low-cost components to reduce total BOM cost. Furthermore, the current limit is fully temperature compensated resulting

ESL IS THE PARASITIC INDUCTANCE OF THE CURRENT-SENSE RESISTOR
Figure 4. Resistor Current Sense

# VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers 

in a constant output current limit over the entire operational temperature range. This eliminates the need to oversize MOSFETs and inductors to compensate for thermal effects. Connecting ILIM to VCC programs the default current-limit threshold. To select a different cur-rent-limit threshold, connect a resistor-divider from REF to GND with ILIM connected to the center tap. The voltage at ILIM is proportional to the current-limit threshold. See the Setting the Current-Limit section for more details.
The current-limit circuitry terminates the $\mathrm{DH}_{-}$on-time immediately when the current-sense voltage (VCS_+ $V_{C S}{ }^{-}$) exceeds the current-limit threshold, allowing the output inductor current to ramp down. At the next switching cycle, the PWM pulse is skipped if the output inductor current is still above the current-limit threshold. Otherwise, the new cycle initiates as normal.
The MAX8809A/MAX8810A offer foldback-current protection under soft-start and overload conditions. This feature allows the VRM to safely operate under shortcircuit conditions and to automatically recover once the short-circuit condition is removed. If the output voltage falls below the VRREADY threshold during an overcurrent event, the foldback current-limit circuitry sets the current-limit threshold to half the user-selected value.

Output Differential Sensing (RS+, RS-) The MAX8809A/MAX8810A feature differential outputvoltage sensing to achieve the highest possible output accuracy. This allows the controllers to sense the actual voltage at the load, so the controller can compensate for losses in the power output and ground lines. Traces from the load point back to RS+ and RS- should be routed close to each other and as far away as possible

Figure 5. Recommended Filtering for Output-Voltage Remote Sensing
from noise sources (such as inductors and high di/dt traces). Use a ground plane to shield the remote-sense traces from noise sources. To filter out common-mode noise, RC filtering is recommended for these inputs as shown in Figure 5. For VRD applications, a $100 \Omega$ resistor with a 1 nF capacitor should be used. For VRM applications, additional $50 \Omega$ resistors should be connected from these inputs to the local outputs of the converter before the VRM connector. This avoids excessive voltage at the CPU in case the remote-sense connections get disconnected.

## Programming the Output-Voltage Droop

Both the MAX8809A and MAX8810A employ peak-cur-rent-mode control with finite gain to actively set the out-put-voltage droop. Figure 6 shows the simplified control block diagram. The relationship between the output inductor current in an N -phase DC-DC converter and the output voltage of the voltage-error amplifier is:

$$
V_{\mathrm{C}}=\frac{\mathrm{I}_{\mathrm{OUT}}}{\mathrm{~N}} \times \mathrm{R}_{\text {SENSE }} \times \mathrm{G}_{\mathrm{CA}}
$$

where GCA (30V/V typ) is the gain of the differential current amplifier and $N$ is the number of phases. IOUT is the total output current. Therefore, when the output current increases, $\mathrm{V}_{\mathrm{C}}$ increases. On the other hand, $\mathrm{V}_{\mathrm{C}}$ is related to the output voltage of the converter by the following equation:

$$
V_{C}=g_{M V} \times R_{C O M P} \times\left(V_{D A C}-V_{\text {OUT }}\right)
$$

where $g_{M V}$ is the transconductance of the voltage-error amplifier ( 2 mS typ) and VDAC is the VID-generated voltage.

Figure 6. Simplified Peak Current-Mode Control IC with Active Output-Voltage Positioning

## VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers

The DC gain of the voltage-error amplifier is equal to $\mathrm{gmV}_{\mathrm{MV}} \times$ RCOMP. From the previous equations it is clear that the output-voltage droop can be accurately programmed if the DC gain of the voltage-error amplifier is set to be a finite value. As the output current increases, $V_{C}$ increases and, consequently, VOUT decreases. Define the output-droop resistance, RDROOP, as:

$$
R_{\text {DROOP }}=\frac{\left(V_{\text {DAC }}-V_{\text {OUT }}\right)}{I_{\text {OUT }}}
$$

then RDROOP can be expressed as:

$$
R_{\text {DROOP }}=\frac{R_{\text {SENSE }} \times G_{C A}}{N \times g_{M V} \times R_{C O M P}}
$$

Since GCA and $g_{M V}$ are constants, RDROOP is solely determined by RCOMP when RSENSE and N are chosen.
Peak current-mode control with finite gain is the simplest way to achieve the output-voltage droop without introducing a separate current loop, which is the case for voltage-mode control. Therefore, the response time of the output-voltage droop is the same as the voltagefeedback loop, resulting in fast output-voltage-droop transient response and less output capacitance than solutions using voltage-mode control.
Other features offered by peak-current-mode control are excellent line regulation and inherent current sharing between phases. Standard peak-current-mode control does have one disadvantage in that current matching between phases is impacted by the inductor mismatch (tolerance) between phases. Because only the current peak is controlled, any mismatch in the inductor value between two phases creates an inductor ripple current mismatch, which, in turn, creates a DC current mismatch between those two phases. Tolerance mismatch between the current-sense capacitors used in DCR current sensing creates the exact same DC current mismatch as an inductor mismatch.
Maxim's proprietary RA² technology addresses this issue by averaging out the inductor ripple current individually at each phase, as shown in Figure 7. The rapid active average circuitry learns the peak-to-peak ripple current of each phase in 5 to 10 switching cycles and then biases the peak current signal down by half of the peak-to-peak ripple current, consequently eliminating the impact of both output inductance and DCR currentsense capacitance variations. Since the rapid active

Figure 7. Implementation of the Rapid Active Averaging (RA²) Algorithm
average circuitry is not part of the current-loop path, it does not slow down the transient response.

## Programming the Output Offset Voltage

According to the Intel VRD specifications, the output voltage at no load cannot exceed the voltage specified by the VID code, including the initial set tolerance, ripple voltage, and other errors. Therefore, the actual output voltage should be biased lower to compensate for these errors. For the MAX8809A, the output-voltage offset is created through a resistor-divider that is connected between REF and GND, with the center tap connected to COMP as shown in Figure 8. This resistordivider also sets the output load-line. The MAX8810A contains a BUF output that makes the output-voltage offset setting independent of the output load-line. To program the output-voltage offset, connect a resistor between COMP and GND. A resistor between BUF and COMP sets the output load-line. See the Loop Compensation Design section for details on setting the output-voltage offset.

# VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers 

Figure 8. Programming the Output Offset Voltage

## Load-Line Independent Inductor DC Resistance Temperature Compensation

 Changes in inductor resistance due to temperature cause a change in the output-droop characteristic. This is compensated by changing the gain of the currentsense amplifier as a function of temperature. In doing so, the voltage at COMP is independent of temperature, resulting in a temperature-independent load-line setting. Additionally, the output short-circuit protection is also temperature independent because current limit is implemented by clamping the voltage at COMP. This technology uses an NTC thermistor solely for temperature compensation, freeing it from being one of the components that determines the output load-line. Therefore, only one NTC thermistor is needed to enable any output load-line. The same NTC thermistor is used for temperature sense for the VRHOT output. The MAX8809A/ MAX8810A temperature-compensation scheme is optimized for use with a Panasonic ERTJ1VR103 10k $\Omega$ NTC thermistor. Other thermistors may be used. Contact your local Maxim representative for more details.
## Loop Compensation

During a load transient, the output voltage instantly changes due to the ESR of the output capacitors by an amount equal to their ESR times the change in load current $\left(\Delta V_{\text {OUT }}=R_{E S R} \times \Delta l_{\text {LOAD }}\right)$. The output voltage then deviates further based on the speed at which the loop compensates for the load transient. The voltage-positioning method allows better utilization of the output regulation window, resulting in less required output capacitors. The RA² architecture adjusts the output current based on the instantaneous output voltage, resulting in fast voltage positioning. The voltage-error amplifier consists of a high-bandwidth, high-accuracy transconductance amplifier ( $\mathrm{gmv}_{\mathrm{mv}}$ in Figure 7). The nega-
tive input of the transconductance amplifier is connected to the output of the remote-voltage differential amplifier, and the positive input is connected to the output of an internal DAC controlled by the VID inputs. The DC gain of the transconductance amplifier is set to a finite value to achieve fast output-voltage positioning by connecting an RC circuit (RCOMP and CCOMP) from COMP to GND. See the Loop-Compensation Design section for details on selecting the required components.

## VR Ready Output (VRREADY)

VRREADY is an open-drain output that turns high impedance when the output voltage reaches regulation. VRREADY goes low if Vout is less than (VDAC 225 mV ) or greater than (VDAC +175 mV ), signaling an out-of-regulation fault. VRREADY is held low in shutdown, if VCC is less than the UVLO threshold, or during soft-start. For logic-level output voltages, connect an external pullup resistor between VRREADY and the logic power supply. A $100 \mathrm{k} \Omega$ resistor works well in most applications.

Dynamic VID Change The MAX8809A/MAX8810A provide the ability for the CPU to dynamically change the VID inputs while the controller is operating (on-the-fly or OTF). The output voltage changes in 6.25 mV steps (Intel) or $12.5 \mathrm{mV} / 25 \mathrm{mV}$ steps (AMD) when a VID change is detected.
The controller provides a 400ns logic-skew window to prevent false code changes. The controller accepts both step-by-step changes of VID inputs or all-at-once VID input changes. For all-at-once VID input changes, the output-voltage slew rate is the same, 1 LSB per step and $2 \mu$ s duration. VRREADY is blanked during dynamic VID changes.

## Multiphase Operation Selection

The MAX8809A operates in either a 2- or 3-phase configuration. Connect PWM3 to $\mathrm{V}_{\mathrm{CC}}$ for 2-phase operation.
The MAX8810A operates in 2-, 3- or 4-phase configuration. Connect PWM4 to Vcc for 3-phase operation. Connect PWM4 and PWM3 to VCc for 2-phase operation. All active PWM outputs are held low during shutdown.

UVLO and Output Enable When the IC supply voltage ( $\mathrm{V}_{\mathrm{CC}}$ ) is less than the UVLO threshold ( 4.25 V typ), all active PWM outputs are internally pulled low and most internal circuitry is shut down to reduce the quiescent current. When EN is released and $\mathrm{V}_{\mathrm{C}}>$ UVLO, the internal $100 \mathrm{k} \Omega$ resistor pulls EN to VCC and soft-start is initiated (after a typical 2.2 ms delay).

## VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers

When the driver supply voltage $\left(\mathrm{V}_{\mathrm{V}} \mathrm{L}_{-}\right)$is less than its UVLO threshold ( 3.55 V typ), $\mathrm{DH}_{-}$and $\mathrm{DL}_{-}$are held low. If $\mathrm{V}_{\mathrm{VL}}$ is above the UVLO threshold and while EN is low, $\mathrm{DL}_{-}$is driven high and $\mathrm{DH}_{-}$is held low. This prevents the output of the converter from rising before a valid EN high signal is present.

## Soft-Start

The MAX8809A/MAX8810A soft-start with 6.25 mV steps, regardless of processor architecture. Connect a resistor between SS/OVP and GND to program the softstart time. When the device is enabled, SS/OVP is driven to 2 V and the current drawn by the set resistor is measured. This current sets the internal delay time between the DAC voltage steps. Select a resistor between $12 \mathrm{k} \Omega$ and $90.9 \mathrm{k} \Omega$ for a corresponding soft-

Table 1. Intel Startup Sequence Specifications

| PARAMETER | MIN | MAX |
| :---: | :---: | :---: |
| TD1 | 1 ms | 5 ms |
| TD2 | $50 \mu \mathrm{~s}$ | 5 ms |
| TD3 | $50 \mu \mathrm{~s}$ | 3 ms |
| TD4 | - | 2.5 ms |
| TD5 | $50 \mu \mathrm{~s}$ | 3 ms |

start time of $500 \mu$ s to 6.5 ms . For Intel designs, the resistor value is calculated as:

$$
R_{S S / O V P}(k \Omega)=\frac{t_{S S}-0.0183}{0.0532}
$$

where tss is the desired soft-start time (in ms) to the 1.1V $V_{\text {BOOT }}$ level. Figure 9 shows the Intel startup sequence, and Table 1 shows the values of the time delays.
For AMD applications, the controllers soft-start up to the voltage set by the VID inputs. The soft-start time is set by the following equation:

$$
R_{S S / O V P}(k \Omega)=\frac{t_{S S}-0.0183}{0.0532} \times \frac{1.1 \mathrm{~V}}{V_{D A C}}
$$

where $\mathrm{V}_{\mathrm{DAC}}$ is the output voltage set by the VID inputs. Figure 10 shows the AMD startup sequence, and Table 2 shows the values of the time delays.

Soft-Stop
When EN goes low, the output of the converter ramps down to 0 V in 6.25 mV DAC steps in the time set by the SS/OVP input. Once the output reaches OV, DL is held high and DH is held low to maintain the OV output. This

| TD4 | - | 500 |

*User programmable.
approach prevents large negative voltages on the output during shutdown and therefore eliminates the need for a Schottky clamp diode on the output.

Output Overvoltage Protection (OVP)
When the output voltage exceeds the regulation voltage by 200 mV (Intel) or exceeds 1.8 V (AMD), all active PWM outputs are pulled low and the controller is latched off. SS/OVP is internally pulled to VCC to signal an overvoltage fault. All DH_ outputs are held low and all DL_ outputs are held high to discharge the output. The latch condition can only be cleared by cycling the input voltage ( $V_{C C}$ ).

## Integrated Dual-MOSFET Driver

The MAX8809A/MAX8810A contain a dual-phase gate driver capable of driving 3000 pF capacitive loads with only 32 ns propagation delay and 11ns typical rise and fall times, allowing operation up to 1.2 MHz per phase. Adaptive dead time controls low-side MOSFET turn-on and high-side MOSFET turn-on. This maximizes converter efficiency, while allowing operation with a variety of MOSFETs. A UVLO circuit ensures proper power-on sequencing.

## Adaptive Shoot-Through Protection

Adaptive shoot-through protection is incorporated for the switching transition after the high-side MOSFET is turned off and before the low-side MOSFET is turned on. The low-side driver is turned on only when the LX voltage falls below 2.5 V typical. In addition, a fixed 35ns delay time between the low-side MOSFET turn-off and high-side MOSFET turn-on adds further protection from "shoot-through." The 35ns time begins after DL_ has fallen through 1.5 V typical.

MOSFET Driver UVLO
When VVL12 (MAX8809A) or VVL1 (MAX8810A) is below the UVLO threshold (3.55 typ), DH_ and DL_ are held

# VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers 

low. Once $\mathrm{VVL}_{-}$is above the UVLO threshold and EN is low, $\mathrm{DL}_{-}$is kept high and $\mathrm{DH}_{-}$is kept low. This prevents the output from rising before a valid EN signal is given.

## Boost Circuit for High-Side MOSFET Driver

 The gate-drive voltage for the high-side MOSFET drivers is generated by a flying-capacitor boost circuit. The capacitor between BST_ and LX_ is charged from the VL_ supply through an internal switch while the lowside MOSFET is on. When the low-side MOSFET is switched off, the stored voltage on the capacitor is stacked above LX_ to provide the necessary turn-on voltage for the high-side MOSFET(s). No external boost diode is needed. See the Boost Capacitor Selection section for details on selecting the correct capacitor.
## Thermal Protection

The MAX8809A/MAX8810A feature a thermal-fault-protection circuit. When the junction temperature rises above $+160^{\circ} \mathrm{C}$ typical, an internal thermal sensor activates the shutdown circuit to hold all MOSFET drivers and active PWM outputs low to disable switching. The thermal sensor reactivates the controller after the junction temperature cools by $25^{\circ} \mathrm{C}$ typical.

Temperature Monitoring (VRTSET, VRHOT)
The MAX8809A/MAX8810A contain temperature-monitoring circuitry that allows the user to program a temperature trip point between $+60^{\circ} \mathrm{C}$ and $+125^{\circ} \mathrm{C}$, and

Table 3. Temperature Scale Factor

| TEMPERATURE ( ${ }^{\circ} \mathbf{C}$ ) | $\mathbf{K}_{\mathbf{T}}$ | RVRTSET $^{\mathbf{( k} \Omega} \mathbf{)}$ |
| :---: | :---: | :---: |
| +60 | 4.497 | 294 |
| +65 | 5.453 | 243 |
| +70 | 6.580 | 200 |

| +105 | 21.643 | 61.9 |
| +110 | 25.247 | 52.3 |
| +115 | 29.345 | 45.3 |
| +120 | 33.988 | 39.2 |
| +125 | 39.231 | 34 |

monitor an active-high, open-drain VRHOT output. Connect a resistor from VRTSET to GND to set the tem-perature-monitoring threshold. The resistor is calculated as follows:

$$
R_{\mathrm{VRTSET}}=\frac{800}{0.6 \mathrm{~K}_{\mathrm{T}}} \text { in } \mathrm{k} \Omega
$$

where $\mathrm{K}_{T}$ is a temperature scale factor specifically for the Panasonic ERTJ1VR103 NTC thermistor. Table 3 provides values of $\mathrm{K}_{\mathrm{T}}$ and the closest standard $1 \%$ RVRTSET values needed to program the VRHOT threshold over a $+60^{\circ} \mathrm{C}$ to $+125^{\circ} \mathrm{C}$ range. RVRTSET must be greater than $20 \mathrm{k} \Omega$. Contact your local Maxim representative for information on using other thermistors.

## Architecture Selection and Timing

## AMD K8 Rev F

The AMD K8 Rev F processor uses a 6-bit VID code that specifies a 0.375 V to 1.55 V output voltage range (see Table 4). Leave SEL unconnected to select the AMD K8 Rev F architecture. The startup sequencing and timing specifications are shown in Figure 10. Note that the VID input defines the AMD processor boot level, and there is no internal default. The boot level is not latched; therefore, if the codes change during softstart, the boot level also changes.

Extended Intel VRD10
The Intel VRD10 processor uses a 7-bit VID code that specifies a 0.83125 V to 1.6 V output voltage range (see Table 5). Connect SEL to GND to select the VRD10 architecture. The startup sequencing and timing specifications are shown in Figure 9. The Intel boot level is internally set to 1.1 V ; therefore, the VID inputs are ignored during soft-start. In compliance with the Intel VRD specifications, there is a typical 2.2 ms delay after EN is asserted before soft-start begins. This delay is not included in the soft-start time set by SS/OVP.

Intel VRD11
The Intel VRD11 processor uses an 8-bit VID code that specifies a 0.3125 V to 1.6 V output voltage range (see Table 6). Connect SEL to VCC to select the VRD11 architecture. The startup sequencing and timing specifications are shown in Figure 9. The Intel boot level is internally set to 1.1 V ; therefore, the VID inputs are ignored during soft-start. In compliance with the Intel VRD specifications, there is a typical 2.2 ms delay after EN is asserted before soft-start begins. This delay is not included in the soft-start time set by SS/OVP.

## Design Procedure

The following sections detail the selection process for the external components used with the MAX8809A/ MAX8810A. Contact your local Maxim representative to obtain a spreadsheet-based tool to facilitate your design.

Setting the Switching Frequency
The switching frequency influences the switching loss, the size of the power MOSFETs, and the size of power components such as output inductors and capacitors. Higher switching frequencies result in smaller external components and more compact designs. However, power-MOSFET switching losses and magnetic core losses in the output inductor increase with switching frequency, reducing efficiency. Select a switching frequency as a tradeoff between size and efficiency. Once the per-phase switching frequency is selected, the internal oscillator frequency (fosc) must be set. Determine the required oscillator frequency based on the desired per-phase switching frequency (fsw) from Table 7.

Table 7. Required Clock Frequency for Per-Phase Switching Frequency

| NO. OF <br> PHASES | CONFIGURATION | fosc |
| :---: | :--- | :---: |
| 2 | PWM3 $=V_{C C}(M A X 8809 A) ;$ <br> PWM3 $=P W M 4=V_{C C}(M A X 8810 A)$ | $4 \times f \mathrm{fW}$ |
| 3 | PWM4 $=\mathrm{V}_{\mathrm{CC}}(\mathrm{MAX8810A})$ | $3 \times \mathrm{fsw}$ |
| 4 | MAX8810A only | $4 \times \mathrm{fsw}$ |

For 2- or 4-phase designs, the internal clock frequency should be set at four times the desired per-phase switching frequency. In 3-phase designs, the internal clock frequency should be set at three times the desired per-phase switching frequency. Set the internal clock frequency with a resistor from OSC to GND (Rosc). The value of Rosc for a given internal clock frequency is approximated from the following equation:

$$
\mathrm{R}_{\mathrm{OSC}}=161.88 \times \mathrm{fosc}^{-1.2074}
$$

# VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers 

where fosc is given in MHz and ROSC is in $\mathrm{k} \Omega$. Also see the Per-Phase Frequency vs. ROSC graph in the Typical Operating Characteristics for the relationship between the clock frequency and the value of the fre-quency-setting resistor.

Output Inductor Selection
The output inductor is selected based on the desired amount of inductor ripple current. A larger inductance value minimizes output ripple current and increases efficiency but slows down the output-inductor-current slew rate during a load transient. LIR is the ratio of ripple current to the total current per phase. For the best tradeoff of size, cost, and efficiency, an LIR of $30 \%$ to $60 \%$ is recommended (LIR $=0.3$ to 0.6). Choose a higher LIR when more phases are used to take advantage of ripple-current cancellation. The inductor value is determined from:

$$
\mathrm{L} \geq \frac{\mathrm{V}_{\text {OUT }} \times(1-\mathrm{D}) \times \mathrm{N}}{\text { LIR } \times f_{\text {SW }} \times \text { loUT_MAX }^{2}}
$$

where fsw is the per-phase switching frequency, IOUT_MAX is the maximum-rated output current, D is the duty ratio, $N$ is the number of phases, and Vout is the output voltage at a given VID code. The output-inductor ripple current produces a ripple voltage across the out-put-capacitor ESR that usually is the dominant component of the output voltage ripple. For an N-phase buck converter with a $\mathrm{D} \times \mathrm{N}$ factor of less than 1, the output ripple voltage, VRIPPLE, can be calculated using:

$$
V_{\text {RIPPLE }}=\frac{V_{\text {OUT }} \times R_{\text {ESR_CO }} \times(1-(\mathrm{D} \times \mathrm{N}))}{\mathrm{f}_{\text {SW }} \times \mathrm{L}}
$$

This equation takes into account the voltage ripple cancellation from multiphase designs. Optimum voltage positioning (droop) requires the effective output-capacitor ESR to match the load resistance, Ro. For initial rip-ple-voltage estimates, replace ReSR_Co with Ro. If the output-ripple-voltage specification is not satisfied, a larger value of output inductance should be chosen. The selected inductor should have the lowest possible DC resistance, and the saturation current should be greater than the peak inductor current, IPEAK. IPEAK is found from:

$$
\text { IPEAK }=\frac{\text { IOUT_MAX }}{N} \times\left(1+\frac{\text { LIR }}{2}\right)
$$

When the $D C$ resistance (RDC) of the output inductor is used for current sensing, the DC resistance should be a minimum of $0.5 \mathrm{~m} \Omega$.
It is also important that the peak-to-peak ripple voltage at the input of the current-sense amplifier not exceed 23 mV :

(VCS+ - VCS-) $=$ IRIPPLE $\times$ RSENSE

where RSENSE is the sense resistance value at the highest operating temperature. If this condition is not met, then the LIR must be adjusted or the input signal to the current-sense amplifier must be scaled down with a resistor-divider.

## Output Capacitor Selection

In most cases, selection of the output capacitor is dictated by the target ESR requirement, RESR_CO = Ro (load resistance), to meet the core-supply transient response. However, the minimum output capacitance, $\mathrm{CO}(\mathrm{MIN})$, required to meet load-dump requirements, is estimated based on energy balance from:

$$
\mathrm{CO}_{\mathrm{OMIN})} \geq \frac{1}{2} \times \frac{\mathrm{L} \times\left(\mathrm{IINIT}^{2}-\operatorname{IFIN}^{2}\right)}{\mathrm{N} \times\left(\mathrm{V}_{\mathrm{FIN}}-\mathrm{V}_{\text {INIT }}+\mathrm{VOV}\right) \times \mathrm{V}_{\text {INIT }}}
$$

where IINIT and IFIN are the initial and final values of the inductor current during a load dump, VINIT is the voltage prior to the load dump, VFIN is the voltage after, and Vov is the allowed overshoot above VFIN. The above equation is an approximation, and the outputcapacitance value obtained serves as a good starting point. The final value should be obtained from actual measurements.
There is also an upper limit on the amount of output capacitance to meet the OTF VID change requirement. Too much output capacitance can prevent the output voltage from reaching the new VID output voltage within the OTF time window:

$$
C_{\text {O(MAX) }} \leq \frac{(\text { lLIM }- \text { l OUT_MAX }) \times \text { toTF }}{\Delta V_{\text {OTF }}}
$$

where tOTF is the time window to achieve $\Delta \mathrm{V}_{\text {OTF }}$ (change in output voltage). If $\mathrm{CO}(\mathrm{MAX})$ is less than $\left.\mathrm{CO}_{(\text {MIN }}\right)$, the system does not meet the VID OTF specification. ILIM is usually set at $110 \%$ to $120 \%$ of lout_MAX.
RMS ripple current rating is an additional requirement for the output capacitors. For a multiphase buck converter, the RMS ripple current in the output capacitors is given by:

$$
\mathrm{I}_{\mathrm{CO}} \text { RMS }=\frac{\mathrm{V}_{\text {OUT }} \times(1-\mathrm{N} \times \mathrm{D})}{2 \sqrt{3} \times \mathrm{L} \times \mathrm{f}_{\text {SW }}}
$$

for $(\mathrm{N} \times \mathrm{D}) \leq 1$, where D is the duty cycle and is computed from the following equation:

$$
\mathrm{D}=\frac{\mathrm{N} \times \mathrm{V}_{\text {OUT }}+\text { l OUT_MAX } \times\left(\mathrm{R}_{\text {DSON_LS }}+\mathrm{R}_{\mathrm{DC}}\right)}{\mathrm{N} \times \mathrm{V}_{\mathrm{IN}}-\text { loUT_MAX } \times\left(\mathrm{R}_{\text {DSON_HS }}-\mathrm{R}_{\text {DS_LO }}\right)}
$$

# VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers 

Use the maximum input voltage for calculating the duty cycle to obtain the worst-case RMS ripple current. RDSON_LS and RDSON_HS are the on-state resistances of the low-side and high-side MOSFETs, respectively, and $\mathrm{R}_{\mathrm{DC}}$ is the DC resistance of the output inductor.

## Input Capacitor Selection

The input capacitor reduces the peak current drawn from the power source and reduces the noise and voltage ripple on the input DC voltage bus caused by the circuit's switching. The input capacitors must meet the ripple-current requirement (IRMS) imposed by the switching currents as defined by the following equation:

$$
I_{\text {RMS }}=D \times \text { IOUT_MAX } \times \sqrt{\frac{1}{N \times D}-1}
$$

for $(\mathrm{D} \times \mathrm{N}) \leq 1$
Use the minimum input voltage for calculating the duty cycle to obtain the worst-case input-capacitor RMS ripple current. Low-ESR aluminum electrolytic, polymer, or ceramic capacitors should be used to avoid large voltage transients at the input during a large step load change at the output. The ripple-current specifications provided by the manufacturer should be carefully reviewed for temperature derating. Additional smallvalue, low-ESL ceramic capacitors ( $1 \mu \mathrm{~F}$ to $10 \mu \mathrm{~F}$ with proper voltage rating) can be used in parallel to reduce any high-frequency ringing.

## Boost Capacitor Selection

The MAX8809A/MAX8810A use a bootstrap circuit to generate the floating supply voltages for the high-side drivers. The selected high-side MOSFET determines the appropriate boost capacitance values according to the following equation:

$$
\mathrm{C}_{\mathrm{BST}}=\frac{\mathrm{Q}_{\mathrm{GATE}} \mathrm{HS} \times \mathrm{M}_{\mathrm{HS}}}{\Delta \mathrm{~V}_{\mathrm{BST}}}
$$

where $M_{H S}$ is the total number of high-side MOSFETs handled by each BST_ capacitor, QGATE_HS is the total gate charge of each high-side MOSFET, and $\Delta \mathrm{V}_{\text {BST }}$ is the voltage variation allowed on the high-side MOSFET drive. Choose $\Delta \mathrm{V}_{\mathrm{BST}}=0.1 \mathrm{~V}$ to 0.2 V when determining the CBST_ value. Use low-ESR ceramic capacitors for CBST_. Note that QGATE_HS is a function of gate-drive voltage $\mathrm{VVL}_{\mathrm{V}}$ and should be obtained from the MOSFET data sheet $V_{G S}$ vs. QGATE curve.

## VL_ Bypass Capacitor Selection

VL_ provides the supply voltages for the low-side drivers. The decoupling capacitor at $V L_{-}$also charges the high-side driver's BST capacitor during the time period
when the low-side MOSFET is turned on. Therefore, the decoupling capacitor for $\mathrm{VL}_{-}$should be large enough to minimize the ripple voltage during switching transitions. Choose CVL_ according to the following equation:

$$
\mathrm{C}_{\mathrm{VL}_{-}}=10 \times \mathrm{C}_{\mathrm{BST}_{-}}
$$

Power-MOSFET Selection
MOSFET power dissipation depends on the gate-drive voltage ( $\mathrm{V}_{\mathrm{D}}$ ), the on-resistance (RDSON), the total gate charge (QGATE), and the gate threshold voltage ( $\mathrm{V}_{\mathrm{TH}}$ ). The supply voltage (VL_) range for the MOSFET drivers is from 4.5 V to 7 V . With $\mathrm{VGATE}<10 \mathrm{~V}$, logic-level threshold MOSFETs are recommended.
Power dissipation in the high-side MOSFET consists of two parts: the conduction loss and the switching loss. The per phase conduction loss for the high side can be calculated from:

$$
P_{C O N D} \text { _HS }=D \times \frac{\stackrel{I}{\mathrm{OUT}}_{2}^{2} M A X}{N^{2}} \times\left(1+\frac{\text { LIR }^{2}}{12}\right) \times \frac{R_{\text {DSON_HS }}}{M_{H S}}
$$

where N is the number of phases and MHS is the number of MOSFETs in parallel for each phase. Total highside conduction loss equals the number of phases times PCOND_HS.
Switching loss is the major contributor to the high-side MOSFET power dissipation due to the hard switching transition every time it turns on. The switching loss is found from the following:

$$
P_{S W} \text { _HS }=\frac{2 \times V_{\mathbb{N}} \times I_{\text {OUT_MAX }}}{N} \times \frac{R_{\text {GATE }} \times Q_{\text {MILLER }}}{V_{D}-V_{T H}} \times f_{S W} \times M_{H S}
$$

where $V_{D}$ is the gate-drive voltage and RGATE is the total gate resistance including the driver's on-resistance (see the Electrical Characteristics table) and the MOSFET gate resistance. For a logic-level power MOSFET, the gate resistance is approximately $2 \Omega$. QMILLER is the MOSFET Miller charge found in the MOSFET data sheet. Note that adding more MOSFETs in parallel on the high side increases the switching loss. Smaller Miller gate charge and lower gate resistance usually result in lower switching loss.
The low-side MOSFET power dissipation is mostly attributed to the conduction loss. Switching loss is negligible due to the zero-voltage switching at turn-on and body-diode clamp at turn-off. Power dissipation in the low-side MOSFETs of each phase can be calculated from the following equation:

$$
\text { PCOND_LS }=(1-D) \times \frac{\text { R}^{2} \text { OUT_MAX }}{N^{2}} \times\left(1+\frac{\text { LIR }^{2}}{12}\right) \times \frac{R_{\text {DSON_LS }}}{M_{\text {LS }}}
$$

# VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers 

where MLS is the number of MOSFETs in parallel per phase on the low side. Total power dissipation for the low side equals the number of phases times the lowside conduction loss of each phase.
Even though the switching loss is insignificant in the low-side MOSFETs, RDSON is not the only parameter that should be considered in selecting the low-side MOSFETs. Large Miller capacitance (CRSS) could turn on the low-side MOSFETs momentarily when the drain-to-source voltage goes high at fast slew rates, if the driver cannot hold the gate low. The ratio of CRSS/CISS should be less than 1/10th for the low-side MOSFETs to avoid shoot-through current due to momentary turn-on of the low-side switch. Adding a resistor between BST_ and CBST_ can slow the high-side MOSFET turn-on. Similarly, adding a capacitor from the gate to the source of the high-side MOSFET has the same effect. However, both methods are at the expense of increasing the high-side switching losses.

## Loop-Compensation Design

Loop Compensation with Voltage Positioning
Processor power-supply specifications often require the output voltage to "droop" from its no-load value at a fixed slope with increasing load current. This slope is termed the load-line resistance (Ro). Once the currentsense resistance (RSENSE), the required load-line resistance, and the output offset voltage (VOS) are determined, the values of RLL and ROS (see Figure 8) are calculated from the following equations:
For the MAX8809A:

$$
\begin{gathered}
R_{L L}=\frac{1}{\frac{g_{M V}}{2} \times\left(\frac{N \times R_{O}}{R_{S E N S E} \times G_{C A}}-V_{O S}\right)} \\
R_{\mathrm{OS}}=\frac{1}{\frac{g_{M V}}{2} \times\left(\frac{N \times R_{O}}{R_{S E N S E} \times G_{C A}}+V_{O S}\right)-\frac{1}{20 \times 10^{6}}}
\end{gathered}
$$

For the MAX8810A:
The 1V BUF output simplifies the Ros calculation considerably. ROS and RLL are calculated as:
where:

$$
\begin{gathered}
\mathrm{R}_{\mathrm{OS}}=\frac{1}{g_{\mathrm{MV}} \times \mathrm{V}_{\mathrm{OS}}} \\
\mathrm{R}_{\mathrm{LL}}=\frac{\mathrm{R}_{\mathrm{OS}} \times \mathrm{R}_{\mathrm{COMP}}}{\mathrm{R}_{\mathrm{OS}}-\mathrm{R}_{\mathrm{COMP}}}
\end{gathered}
$$

$$
R_{\text {COMP }}=\frac{R_{\text {SENSE }} \times G_{C A}}{N \times g_{M V} \times R_{O}}
$$

The pole due to the load (ROUT) and output capacitance produces a $-20 \mathrm{~dB} /$ decade slope up to the output-
capacitor ESR zero frequency. To continue to roll off the gain out to high frequencies at $-20 \mathrm{~dB} / \mathrm{decade}$, the compensation places a pole at the ESR zero frequency. An RC circuit, RCOMP and CCOMP, must be connected from COMP to ground. Calculate RCOMP as the parallel combination of RLL and ROS. The capacitor value can be found from the following equation once the output capacitor ESR is known:

$$
\mathrm{C}_{\mathrm{COMP}}=\frac{\mathrm{R}_{\text {ESR_CO }} \times \mathrm{C}_{\mathrm{O}}}{R_{\mathrm{COMP}}}
$$

where RESR_CO is the total equivalent series resistance and Co is the total capacitance of the output capacitors.

Loop Compensation with Integral Feedback For applications that do not implement droop, it is necessary to compensate the loop using integral feedback. Looking at the transfer function from inductor current iL(t) to output:

$$
\mathrm{G}_{\mathrm{VI}}(\omega)=\mathrm{R}_{\mathrm{OUT}} \times \frac{1+\frac{\omega}{\omega_{Z E R O}}}{1+\frac{\omega}{\omega_{\text {POLE }}}}
$$

The DC gain is the output impedance ROUT:
ROUT = VOUT / IOUT_MAX

A pole and zero are present due to the output capacitance (Co), output-capacitor ESR (RESR_CO), and the load impedance (ROUT), as follows:

$$
\Omega \text { POLE }=\frac{1}{(\text { ROUT }+ \text { RESR_CO }) \times \mathrm{CO}^{2}}
$$

and:

$$
\Omega \text { ZERO }=\frac{1}{\frac{(\text { ROUT } \times \text { RESR_CO })}{(\text { ROUT }+ \text { RESR_CO })} \times \text { CO }^{\prime}}
$$

The transfer function from control voltage $\mathrm{vc}(\mathrm{t})$ to inductor current iL( t ) is:

$$
g_{P W M}=\frac{i_{L}(t)}{v_{C}(t)}=\frac{1}{R_{\text {SENSE }} \times G_{C A}}
$$

where RSENSE is the resistance of the current-sense element, and GCA is the current-sense amplifier gain.
The simplified control-to-output transfer function is then:

$$
\operatorname{GCONTR}_{\text {COUTPUT }}(\omega)=\mathrm{gPWM} \times \mathrm{G}_{\mathrm{VI}}(\omega) \times \mathrm{N}
$$

## VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers

This simplified transfer function ignores a double pole due to the current-mode sampling effect, which can be approximately placed at $1 / 2$ the per-phase switching frequency.
As a rule-of-thumb, the loop should be designed to close between 1/5th and 1/10th of the per-phase switching frequency. At this point, a determination should be made as to which of the following cases applies to the desired crossover frequency:

- Case 1: $\omega$ POLE $<2 \pi \times$ fCROSSOVER $<\omega Z E R O$

This case is likely to exist in situations where the zero frequency ( $\omega$ ZERO) is relatively high due to use of lowvalue output capacitors with low ESR (e.g., $560 \mu \mathrm{~F} / 7 \mathrm{~m} \Omega$ or all-ceramic designs).
Analysis of the control-to-output transfer function for this case shows that 1 ) the slope is -1 at the crossover frequency due to the low-frequency pole ( $\omega$ POLE), and 2) the compensation must provide gain boost at the crossover frequency to bring the loop gain to zero at crossover. Because of item 1), the compensator gain must be flat at crossover so that the closed-loop gain rolls off with -1 slope at crossover.
For this case, it is recommended to design the compensator with type II compensation. The zero is placed to ensure flat gain at crossover, and the 2nd pole provides phase shift above crossover. The compensator consists of a series resistor (RCOMP) and capacitor (CCOMP1) from COMP to GND, and a second capacitor (CCOMP2) placed from COMP to GND, in parallel to RCOMP and CCOMP1 (see Figure 11).
The first step in the compensator design is to choose the desired phase margin at crossover and solve for the error-amplifier phase shift:

$$
\text { фERROR_AMPLIFIER = } \phi M A R G I N ~-~ \phi C O N T R \_O U T P U T ~
$$

where $\phi M A R G I N$ is the desired phase margin at crossover, and фCONTR_OUTPUT is the phase shift from control-to-output (at crossover)

Figure 11. Type II Compensation Scheme

The next step is to determine the constant K value in the equation below, which provides the desired error-amplifier phase shift determined above. The value of K determines the locations of the error-amplifier zero and high-frequency pole relative to the crossover frequency:

$$
\begin{gathered}
\text { QERROR_AMPLIFIER }=\left(\arctan (\mathrm{K})-\arctan \left(\frac{1}{\mathrm{~K}}\right)\right) \times \frac{180}{\pi}+90 \\
\omega_{\text {ZERO_ERROR_AMPLIFIER }}=\frac{2 \pi \times \mathrm{f}_{\mathrm{CROSSO}}}{\mathrm{~K}} \\
\omega_{\text {POLE_ERROR_AMPLIFIER }}=2 \pi \times \mathrm{f}_{\text {CROSSOVER }} \times \mathrm{K}
\end{gathered}
$$

The simplified compensator transfer function can be modeled at low frequencies as:

$$
g_{M V} \times\left(R_{\mathrm{COMP}}+\frac{1}{\omega \times \mathrm{C}_{\mathrm{COMP}}}\right)
$$

where $\mathrm{g}_{\mathrm{MV}}$ is the transconductance of the error amplifier. At crossover, CCOMP1 is essentially a short and can be ignored. The compensator must provide gain boost to bring the loop gain to zero at crossover. Applying these criteria and solving for RCOMP:

$$
\mathrm{R}_{\text {COMP }}=\frac{1}{\mathrm{~g}_{\text {MV }} \times\left|\mathrm{G}_{\text {CONTR_OUTPUT }}\left(\mathrm{f}_{\text {CROSSOVER }}\right)\right|}
$$

Solving for Ccomp1 and CCOMP2 is now relatively straightforward:

$$
\begin{aligned}
& \mathrm{C}_{\text {COMP1 }}=\frac{1}{\omega_{\text {ZERO_ERROR_AMPLIFIER }} \times \mathrm{R}_{\text {COMP }}} \\
& \mathrm{C}_{\text {COMP2 }}=\frac{1}{\omega_{\text {POLE_ERROR_AMPLIFIER }} \times R_{\text {COMP }}}
\end{aligned}
$$

- Case 2: $\omega$ ZERO $<2 \pi \times f$ CROSSOVER $<\omega$ POLE-CM where $\omega$ POLE-CM is the frequency of the double pole created by the sampling effect. This case is likely to exist in situations where high-capacitance, high-ESR output capacitors (e.g., low-cost aluminum electrolytic such as $2800 \mu \mathrm{~F} / 12 \mathrm{~m} \Omega$ ) are used
Analysis of the control-to-output transfer function for this case shows that 1) the slope is zero at crossover so the compensation must roll off with a -1 slope, and 2) the compensation must provide gain boost at the crossover frequency to bring the loop gain to zero at crossover. Both of these conditions are satisfied with the following relationship:

$$
g_{M V} \times \frac{1}{2 \pi \times f_{\text {CROSSOVER }} \times \text { C COMP }}=\frac{1}{\left|G_{\text {CONTR_OUTPUT }}\left(\mathrm{f}_{\mathrm{CROSSOVER}}\right)\right|}
$$

# VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers 

where $\mathrm{g}_{\mathrm{MV}}$ is the transconductance of the error amplifier and CCOMP is a capacitor placed from the output of the error amplifier (COMP) to GND. Solving for CCOMP:

$$
\mathrm{C}_{\text {COMP }}=g_{\mathrm{MV}} \times \frac{\left|\mathrm{G}_{\text {CONTR_OUTPUT }}\left(\mathrm{f}_{\text {CROSSOVER }}\right)\right|}{2 \pi \times \mathrm{f}_{\text {CROSSOVER }}}
$$

## Multiload-Line Programming (MAX8810A)

In some applications, it may be desired to implement multiple load-lines. This is easily accomplished by switching resistors in parallel with RLL (Figure 12). Paralleling resistors with RLL causes the load-line resistance to increase. With this scheme implemented for the MAX8810A, the offset voltage is not affected by the new load-line setting. It is also not necessary to change the temperature compensation based on the new loadline setting. Switches S1 and S2 can be implemented with small-signal n-channel MOSFETs.
RLL1 and ROS are designed using methods described in the Loop-Compensation Design section. RO1, RO2, and RO3 are the required load-line resistances. RLL2 and RLL3 are calculated as follows:

$$
\begin{gathered}
R_{\mathrm{COMP} 1}=R_{\mathrm{LL}} \| R_{\mathrm{OS}} \\
\mathrm{R}_{\mathrm{LL} 2}=\frac{R_{\mathrm{COMP1}} \times R_{\mathrm{COMP}}}{R_{\mathrm{COMP} 1}-R_{\mathrm{COMP} 2}}
\end{gathered}
$$

where:
and:
where:

$$
\mathrm{R}_{\mathrm{COMP} 2}=\frac{\mathrm{R}_{\mathrm{O} 1}}{\mathrm{R}_{\mathrm{O} 2}} \times \mathrm{R}_{\mathrm{COMP} 1}
$$

$$
R_{\mathrm{LL} 3}=\frac{R_{\mathrm{COMP2}} \times R_{\mathrm{COMP3}}}{R_{\mathrm{COMP2}}-R_{\mathrm{COMP3}}}
$$

$$
\mathrm{R}_{\mathrm{COMP3}}=\frac{\mathrm{R}_{\mathrm{O} 2}}{\mathrm{R}_{\mathrm{O} 3}} \times \mathrm{R}_{\mathrm{COMP} 2}
$$

Figure 12. Load-Line Switching Circuit

## Setting the Current Limit

The current-limit threshold sets the maximum available output DC current. The output current limit should be selected to meet the OTF requirement as described in the Output Capacitor Selection section. The voltage at ILIM and the value of the current-sense resistor or the DC resistance of the output inductor sets the currentlimit threshold:

$$
V_{\mathrm{ILIM}}=G_{\mathrm{CA}} \times R_{\text {SENSE }} \times \frac{\mathrm{I}_{\mathrm{LIM}}}{\mathrm{~N}}
$$

where RSENSE is the resistance of the current-sensing element. The value of RSENSE at room temperature must be used because the MAX8809A and MAX8810A provide temperature-compensated current limit. VILIM is set by connecting ILIM to the center tap of a resistordivider from REF to GND. Select R1 and R3 (Figure 13) so the current through the divider is at least $10 \mu \mathrm{~A}$ :

$$
R 1+R 3<200 k \Omega
$$

A typical value for $R 1$ is $10 k \Omega$; then solve for $R 3$ using:

$$
R 3=R 1 \times \frac{V_{\mathrm{LIM}}}{2-\mathrm{V}_{\mathrm{LIM}}}
$$

# VRD11/VRD10, K8 Rev F 2/3/4-Phase PWM Controllers with Integrated Dual MOSFET Drivers 

tering capacitors, which should be placed next to the controller IC. This ensures that noise generated by large di/dt on the LX node is kept away from both cur-rent-sense signals and the controller IC. To ensure the integrity of the current-sense signal, the inner layer above the bottom layer must be a solid ground plane.
Place the VL_ decoupling capacitor on the top layer and near the $\bar{V} L_{-}$pins. The negative terminal of the $V L_{-}$ decoupling capacitor should be connected to PGND_ on the top layer. Also place the BST capacitors on the top layer near the controller. When needed always use double VIAs on the driver traces to reduce inductance. Do not connect the PGND_ pins to the thermal pad on the top layer.
The NTC thermistor should be placed near the "hottest" inductor. Use two traces, tightly coupled, to return to the controller. To ensure temperature compensation accuracy, make sure that the GND trace of the NTC is not "accidentally" connected to any other GND trace or ground plane on the way back to the controller.
Place the BUF capacitor, REF capacitor, VCC capacitor, the current-sense decoupling capacitors, and the remote-sense decoupling capacitors as close to the MAX8809A/MAX8810A as possible. All decoupling capacitors must make a direct connection to the corresponding pin. Making the connection using VIAs to transition between layers creates parasitic inductance, which negates the benefit of the decoupling capacitor. If this cannot be avoided, use double VIAs to minimize the parasitic inductance.
A sample layout is available in the evaluation kit to speed designs.

NOTES:

1. DIMENSIONING \& TILERANCING CINFIRM TI ASME YI4.5M-1994.
2. all dimensions are in millimeters. angles are in degrees.
3. N IS THE TDTAL NUMBER DF TERMINALS.
4. THE TERMINAL \#1 IDENTIFIER AND TERMINAL NUMBERING CONVENTIDN SHALL CONFIRM TO JeSd 95-1 SPP-012. details af terminal \#1 identifier are aptional, but must be located within the zane indicated. the terminal \#1 identifier may be either a mold or marked feature.
5. DIMENSION b APPLIES TO METALLIZED TERMINAL AND IS MEASURED BETWEEN 0.25 mm AND 0.30 mm FRIM TERMINAL TIP.
6. nd and ne refer to the number af terminals an each d and e side respectively.
7. DEPIPULATION IS POSSIBLE IN A SYMMETRICAL FASHION.
8. CIPLANARITY APPLIES TO THE EXPQSED heAt SINK SLUG AS WELL AS THE TERMINALS.
9. DRAWING CINFIRMS TD JEDEC MD22O, EXCEPT FIR 0.4 mm LEAD PITCH PACKAGE T4866-1.
10. WARPAGE SHALL NOT EXCEED 0.10 mm .

亿. marking is for package orientation reference only.
12. NUMBER af LEADS SHOWN FOR REFERENCE $\quad$ ONLY.
